Aromatase inhibitors versus tamoxifen in early breast cancer: patient-level meta-analysis of the randomised trials

Early Breast Cancer Trialists’ Collaborative Group (EBCTCG)*

Summary

Background The optimal ways of using aromatase inhibitors or tamoxifen as endocrine treatment for early breast cancer remains uncertain.

Methods We undertook meta-analyses of individual data on 31920 postmenopausal women with oestrogen-receptor-positive early breast cancer in the randomised trials of 5 years of aromatase inhibitor versus 5 years of tamoxifen; of 5 years of aromatase inhibitor versus 2–3 years of tamoxifen then aromatase inhibitor to year 5; and of 2–3 years of tamoxifen then aromatase inhibitor to year 5 versus 5 years of tamoxifen. Primary outcomes were any recurrence of breast cancer, breast cancer mortality, death without recurrence, and all-cause mortality. Intention-to-treat log-rank analyses, stratified by age, nodal status, and trial, yielded aromatase inhibitor versus tamoxifen first-event rate ratios (RRs).

Findings In the comparison of 5 years of aromatase inhibitor versus 5 years of tamoxifen, recurrence RRs favoured aromatase inhibitors significantly during years 0–1 (RR 0.64, 95% CI 0.52–0.78) and 2–4 (RR 0.80, 0.68–0.93), and non-significantly thereafter. 10-year breast cancer mortality was lower with aromatase inhibitors than tamoxifen (12.1% vs 14.2%; RR 0.85, 0.75–0.96; 2p=0.009). In the comparison of 5 years of aromatase inhibitor versus 2–3 years of tamoxifen then aromatase inhibitor to year 5, recurrence RRs favoured aromatase inhibitors significantly during years 0–1 (RR 0.74, 0.62–0.89) but not while both groups received aromatase inhibitors during years 2–4, or thereafter; overall in these trials, there were fewer recurrences with 5 years of aromatase inhibitors than with tamoxifen then aromatase inhibitors (RR 0.90, 0.81–0.99; 2p=0.045), though the breast cancer mortality reduction was not significant (RR 0.89, 0.78–1.03; 2p=0.11). In the comparison of 2–3 years of tamoxifen then aromatase inhibitor to year 5 versus 5 years of tamoxifen, recurrence RRs favoured aromatase inhibitors significantly during years 2–4 (RR 0.56, 0.46–0.67) but not subsequently, and 10-year breast cancer mortality was lower with switching to aromatase inhibitors than with remaining on tamoxifen (8.7% vs 10.1%; 2p=0.015). Aggregating all three types of comparison, recurrence RRs favoured aromatase inhibitors during periods when treatments differed (RR 0.70, 0.64–0.77), but not significantly thereafter (RR 0.93, 0.86–1.01; 2p=0.08). Breast cancer mortality was reduced both while treatments differed (RR 0.79, 0.67–0.92), and subsequently (RR 0.89, 0.81–0.99), and for all periods combined (RR 0.86, 0.80–0.94; 2p=0.0005). All-cause mortality was also reduced (RR 0.88, 0.82–0.94; 2p=0.0003). RRs differed little by age, body-mass index, stage, grade, progesterone receptor status, or HER2 status. There were fewer endometrial cancers with aromatase inhibitors than tamoxifen (10-year incidence 0.4% vs 1.2%; RR 0.33, 0.21–0.51) but more bone fractures (5-year risk 8.2% vs 5.5%; RR 1.42, 1.28–1.57); non-breast-cancer mortality was similar.

Interpretation Aromatase inhibitors reduce recurrence rates by about 30% (proportionately) compared with tamoxifen while treatments differ, but not thereafter. 5 years of an aromatase inhibitor reduces 10-year breast cancer mortality rates by about 15% compared with 5 years of tamoxifen, hence by about 40% (proportionately) compared with no endocrine treatment.

Introduction

Treatment for 5 years with the selective oestrogen receptor (ER) modulator tamoxifen reduces recurrence rates in ER-positive early breast cancer by about half during treatment and about one-third in the subsequent 5 years, and reduces breast cancer mortality by almost one-third throughout the first 15 years. Further reductions in breast cancer mortality during years 10–14 are achieved by extending tamoxifen treatment to 10 years. In postmenopausal women only, aromatase inhibitors can greatly reduce oestrogen concentrations, hence avoiding stimulation of ER-positive breast cancer cells. Aromatase inhibitors, given either for 5 years or for 2–3 years after 2–3 years of tamoxifen, produce greater reductions in recurrence than 5 years of tamoxifen alone; but the effect on breast cancer mortality, and the optimal way to schedule aromatase inhibitors and tamoxifen in the treatment of early breast cancer, remain uncertain.
American Society of Clinical Oncology (ASCO) clinical practice guidelines reflect this, recommending that postmenopausal women with early ER-positive breast cancer be offered either tamoxifen for 10 years, an aromatase inhibitor for 5 years, tamoxifen initially for 5 years followed by an aromatase inhibitor for up to a further 5 years, or tamoxifen for 2–3 years followed by an aromatase inhibitor for up to a further 5 years. To help clarify the relative benefits of aromatase inhibitors and tamoxifen and the effect of different scheduling during 5 years of endocrine therapy, we undertook collaborative meta-analyses of individual patient data from the trials of aromatase inhibitors versus tamoxifen.

Methods
Identification of studies and collection of data
Trial identification, data checking, analysis, and involvement of trialists are as described in previous Early Breast Cancer Trialists’ Collaborative Group (EBCTCG) reports. Eligible trials began by 2005 and randomised postmenopausal women with ER-positive early breast cancer between 5 years of an aromatase inhibitor versus 5 years of tamoxifen (comparison A); 5 years of aromatase inhibitor versus 2–3 years of tamoxifen, then aromatase inhibitor to year 5 (comparison B); 2–3 years of tamoxifen, then aromatase inhibitor to year 5 versus 5 years of tamoxifen (comparison C); 5 years of aromatase inhibitor versus 2 years of aromatase inhibitor, then tamoxifen to year 5 (comparison D); or 2 years of aromatase inhibitor, then tamoxifen to year 5 versus 5 years of tamoxifen (comparison E). Separate analyses are provided for each of these comparisons (A–E), then results from some of them are combined.

Information was sought during 2012–14 for each individual patient on randomisation date, allocated treatment, age, menopausal status, body-mass index (BMI), tumour diameter, grade, spread to locoregional lymph nodes, ER, progesterone receptor (PR), and HER2 receptor status, and dates of any locoregional, contralateral, or distant breast cancer recurrence, other second primary cancer, bone fractures, death, and cause of death.

Outcomes
The primary outcomes were any recurrence of breast cancer (distant, locoregional, or new primary in the contralateral breast); breast cancer mortality; death without recurrence; and all-cause mortality. Secondary outcomes were incidence and site of second primary cancers, and bone fracture. Prespecified primary subgroup investigations were of site of recurrence, age, nodal status, PR status, histological grade, and follow-up period.

Statistical analyses
Statistical methods (stratified log-rank statistics, Kaplan-Meier graphs) are described elsewhere. Time-to-event analyses were stratified by age, nodal status, and trial. Within each stratum, they compared all those allocated aromatase inhibitor versus all those allocated tamoxifen, regardless of treatment compliance (yielding intention-to-treat analyses). Log-rank statistics were used to assess the effects (aromatase inhibitor vs tamoxifen) on various outcomes, and, for each, to estimate first-event-rate ratios (RRs) and their CIs. If a log-rank statistic (o–e) has variance ν, then, defining z=(o–e)/ν and b=(o–e)/ν, b has variance 1/ν and the event RR (newer treatment vs control) is estimated as exp(b) with SE=(RR–1)/z. CIs for RR are derived from those for b (by normal approximations). 2p indicates two-sided significance. The breast cancer mortality rate in each year is the overall mortality rate among all women minus that among women of similar age without recurrence. Breast cancer mortality RRs are estimated from the corresponding log-rank analyses of mortality with recurrence (obtained by subtracting log-rank analyses of mortality without recurrence [ie, censored at recurrence] from those of overall mortality). Analyses used EBCTCG Fortran programs. The policy on data sharing from this study is available online.

Role of the funding source
The funders of the study had no role in study design, data collection, data analysis, data interpretation, or writing of the report. The secretariat had full access to all data and the writing committee had final responsibility for the decision to submit for publication.

Results
Individual patient datasets were provided for nine trials, including 35 129 (98%) of the 35 718 women randomised between aromatase inhibitor and tamoxifen as part of about 5 years of adjuvant endocrine treatment (appendix). This report is restricted to the 31 920 (91%) with ER-positive tumours of these 35 129 patients. All were randomised evenly between aromatase inhibitor and tamoxifen, though one trial (BIG 1-98) included a four-way randomisation that contributes data to all five comparisons (A–E); the aggregated analyses avoid double counting its results. When reports emerged that patients on tamoxifen had their recurrence risk reduced by switching after 2–3 years to an aromatase inhibitor, crossover to an aromatase inhibitor from the tamoxifen-only group was systematically offered in two trials (BIG 1-98, 25% [619/2459] crossover; ABCSG-8, 18% [341/1949] crossover). In eight trials, compliance was similar in both groups, but in TEAM56% (2698/4814) of those allocated tamoxifen then aromatase inhibitor versus 30% (1438/4852) of those allocated only aromatase inhibitor discontinued treatment prematurely.

In comparison A (5 years of aromatase inhibitor vs 5 years of tamoxifen: two trials, n=9885), recurrence and mortality were both significantly reduced (figure I). The numbers with recurrence were 827 in the aromatase inhibitor group versus 964 in the tamoxifen group (p<0.0001), with separately significant reductions during years 0–1 after surgery (RR 0.64, 95% CI
0·52–0·78) and during years 2–4 (RR 0·80, 0·68–0·93), but no significant further effect after the scheduled treatment period, and little follow-up beyond year 10. The 10-year recurrence risk was 19·1% in the aromatase inhibitor group versus 22·7% in the tamoxifen group (difference 3·6%, 95% CI 1·7–5·5; p<0·0001). Distant recurrence (RR 0·86, 95% CI 0·77–0·96; 2p=0·007), local recurrence (RR 0·74, 0·58–0·95; 2p=0·020), and contralateral recurrence (RR 0·62, 0·48–0·80; 2p=0·0003) were all reduced (appendix). Breast cancer mortality was also reduced (RR 0·85, 95% CI 0·75–0·96; 2p=0·009), as was all-cause mortality (936 vs 1000 deaths; RR 0·89, 0·81–0·97; 2p=0·010), even though half the deaths were from non-breast cancer causes that are little affected by treatment.

In comparison B (5 years of aromatase inhibitor vs 2–3 years of tamoxifen then aromatase inhibitor to year 5: three trials, n=12 779), recurrence was significantly reduced only during years 0–1 (RR 0·74, 95% CI 0·62–0·89; 2p=0·002), ie, when the treatments differed, and was similar during years 2–4 (RR 0·99, 0·85–1·15), when both groups were receiving an aromatase inhibitor (figure 2). There was no significant further effect after year 5, but little follow-up beyond year 7. Perhaps because the period during which the treatments differed lasted only half as long as in comparison A, the absolute reductions in recurrence and mortality appeared smaller. The total numbers with recurrence were 705 in the aromatase inhibitor group versus 765 in the tamoxifen group (2p=0·045). Although breast cancer mortality appeared somewhat reduced (RR 0·89, 95% CI 0·78–1·03; 2p=0·11), this was not significant, and nor were the effects on other mortality or all-cause mortality.

In comparison C (2–3 years of tamoxifen then aromatase inhibitor to year 5 vs 5 years of tamoxifen: six trials, n=11 798), recurrence and mortality were both significantly reduced (figure 3). Four trials did not randomise until after 2 years of tamoxifen, but two randomised at year 0; for comparability with the other four, only patients who completed 2 years of tamoxifen without recurrence or a second primary are included, but sensitivity analyses (appendix) show this exclusion made little difference. Starting from when treatments diverged, the numbers with recurrence were 753 in the aromatase inhibitor group versus 863 in the tamoxifen group (2p=0·0001). Allocation to an aromatase inhibitor reduced the recurrence rate during years 2–4 (RR 0·56, 95% CI 0·46–0·67; p<0·0001), with no significant further effect on recurrence after the treatment period, and little follow-up beyond year 10. The 10-year recurrence risk was 17·0% in the aromatase inhibitor group versus 19·0% in the tamoxifen group (difference 2·0, 95% CI 0·2–3·8). Distant recurrence (RR 0·86, 95% CI 0·77–0·97; 2p=0·02), and contralateral recurrence (RR 0·67, 0·51–0·87; 2p=0·002) were both reduced (appendix). Breast cancer mortality was also reduced (RR 0·84, 95% CI 0·72–0·96; 2p=0·015), as was all-cause mortality (639 vs 764 deaths; RR 0·82, 0·73–0·91; 2p=0·0002), helped by what might have been a chance reduction in non-breast cancer mortality.

The recurrence results already described for comparisons A–C are summarised in the appendix, using black squares for periods when the treatments differed (aromatase inhibitor in one group vs tamoxifen in the other) and open squares for periods when they did not. It also gives the comparisons D and E, which both derive from BIG 1-98. Comparison D was restricted to the 2558 women who were recurrence free and still on treatment after 2 years of aromatase inhibitor. Although they suggest no apparent gain from continuing to take an aromatase inhibitor rather than switching to tamoxifen after 2 years, the CIs were wide. Comparison E included 3060 women; the proportional recurrence reduction during years 0–1 (when the treatments differed) was similar to that in earlier comparisons, and the apparent fluctuations in the recurrence RR during the period when the treatments no longer differed could well be chance.

In each of comparisons A–C there was significant benefit only when treatments differed and not when they were the same in both groups. This pattern is even clearer when results from all five comparisons are aggregated by time period (figure 4). Recurrence RRs favoured aromatase inhibitors during periods when treatments differed (RR 0·70, 95% CI 0·64–0·77), but not significantly thereafter (RR 0·93, 0·86–1·01; 2p=0·08). The recurrence rate was about 30% lower with an aromatase inhibitor than with tamoxifen in years 0–1 (RR 0·70, 95% CI 0·61–0·80; 2p=0·0001), and in years 2–4 (RR 0·71, 0·62–0·80; 2p=0·0001). Combining trials where treatments differed only during years 0–1 and not during years 2–4, there was no reduction in recurrence during years 2–4 (RR 1·03, 95% CI 0·87–1·22). There was little further effect during years 5–9 when no further treatment was scheduled (RR 0·92, 95% CI 0·83–1·01), and little follow-up beyond year 10.

Breast cancer mortality was reduced both while treatments differed (RR 0·79, 95% CI 0·67–0·92), and subsequently (RR 0·89, 0·81–0·99), and for all periods combined (RR 0·86, 0·80–0·94; p=0·0005; appendix). All-cause mortality was likewise reduced (RR 0·90, 95% CI 0·84–0·95; 2p=0·0005).

To enhance statistical power, the main subgroup analyses of recurrence are restricted to the periods when aromatase inhibitor was directly compared with tamoxifen (figure 5). The first such analyses compare the six components from previous figures that contribute to this: the recurrence RRs during years 0–1 were, as expected, similar in comparisons A, B, and E, but the recurrence RRs during years 2–4 appeared somewhat more extreme after 2–3 years of previous tamoxifen (RR 0·56, 95% CI 0·46–0·67) than after 2–3 years of aromatase inhibitor versus tamoxifen (RR 0·83, 0·69–1·00), or after 2 years of aromatase inhibitor (RR 1·08, 0·70–1·68).

Figure 5 subdivides the aggregated result from the periods when treatments differed by aromatase...
inhibitor drug, site of first recurrence, entry age, BMI, and tumour characteristics: PR status, nodal status, tumour diameter, tumour grade, and HER2 status (available for only one-third of patients). The recurrence RRs were similar with different aromatase inhibitors (each \( p<0.0001 \)), with local recurrence, contralateral

breast cancer, and distant recurrence all substantially reduced by aromatase inhibitor compared with tamoxifen. In the aggregated data, the RRs while treatments differed appeared similar in every subgroup, suggesting that age, BMI, and tumour characteristics cannot usefully predict the RR.

Tumour characteristics were, however, importantly predictive of the absolute risk of recurrence, and hence of the absolute effect on breast cancer outcomes of giving an aromatase inhibitor rather than tamoxifen (appendix). For example, in the aggregate of the trials that contribute to the black squares in figure 4, the...
overall Kaplan-Meier estimate of the 5-year recurrence risk was reduced by 2·5% (7·3% vs 9·8%, appendix). But, in this same data set, the 5-year recurrence risks for women with N0, N1–3, and N4+ disease were reduced by 1·2%, 3·7%, and 6·4%, respectively.

Similar sets of subgroup analyses for each separate category of comparisons A–E are in the appendix, but with so many subgroup analyses the apparent findings should be interpreted cautiously, as striking false-positive and false-negative results can easily arise just by chance. For example, the hypothesis from ATAC\(^n\) of a more extreme recurrence RR in ER-positive PR-negative than in ER-positive PR-positive disease is not supported by evidence from other trials (figure 5, appendix). Likewise, the hypothesis from comparison C of equivalent efficacy of aromatase inhibitors and tamoxifen in node-negative disease is not supported by evidence from the other comparisons. Such patterns might be due mainly to chance.

Results for cause-specific mortality, second cancer incidences, and bone fracture during or after any breast cancer recurrence are in the appendix. There was a significant reduction in mortality without recurrence in comparison C (tamoxifen vs aromatase inhibitor) that was not explained by any particular cause and is unlikely to be due to misclassified breast cancer deaths (partly because the non-breast-cancer mortality rates were sharply age-related whereas breast cancer mortality rates were similar in all age groups).

There were fewer uterine cancers and more bone fractures with aromatase inhibitors than with tamoxifen. Aggregating the five comparisons, the 10-year incidence of endometrial cancer (defined as any uterine cancer except cervix cancer) was 0·4% in the aromatase inhibitor group versus 1·2% in the tamoxifen group (absolute difference 0·8%, 95% CI 0·6–1·0; \(p<0·0001\)), including five versus nine deaths. The proportional decrease in endometrial cancer incidence with aromatase inhibitors (RR 0·33, 0·21–0·51) was approximately independent of age and persisted for some years after treatment ended. As endometrial cancer increases with age, the absolute excess with tamoxifen was 0·7% (95% CI 0·5–0·9) at ages 55–69 and 1·4% (95% CI 0·5–2·4) at older ages (appendix). There was no significant effect on any other type of cancer (except for contralateral breast cancer).

The incidence of bone fractures was increased among aromatase-inhibitor-allocated patients during years 0–4 (RR 1·42, 95% CI 1·28–1·57; \(p=0·0001\)), and remained significantly higher through years 5–9 (RR 1·09–1·53; \(p=0·003\)) despite fractures being monitored less reliably after the 5-year treatment period. The 5-year fracture risk was 8·2% in the aromatase inhibitor group versus 5·5% in the tamoxifen group (absolute excess 2·7%, 95% CI 1·7–3·7). Again, the proportional increase appeared approximately independent of age and the absolute incidence increased with age. Hence, among women of age younger than 55, 55–69, and older than 70 years at randomisation, the absolute excess risks (aromatase inhibitor vs tamoxifen) of having a fracture

within 5 years were, respectively, about 1%, 2%, and 4% (appendix). Differences in vascular mortality, aromatase inhibitor versus tamoxifen, were not significant: thromboembolic, 14 versus 19 deaths; cerebrovascular, 44 versus 52 deaths; and cardiac, 137 versus 128 deaths.

**Discussion**

Individual trials have already shown reduced recurrence rates with aromatase inhibitor compared with tamoxifen but none has shown in intention-to-treat analyses that breast cancer mortality is reduced, nor did previous meta-analyses. Now, with longer follow-up, the present meta-analyses establish that breast cancer mortality and all-cause mortality are also reduced, better characterise time-dependent effects on recurrence, and allow informative investigation of differential efficacy within subgroups and of uncommon adverse events.

There was a fairly consistent pattern of substantial recurrence reductions during periods when one group was receiving an aromatase inhibitor and the other tamoxifen, but little further reduction during subsequent periods when both groups were receiving the same endocrine treatment or after scheduled endocrine periods when both groups were receiving the same tamoxifen, but little further reduction during subsequent periods when one group was receiving an aromatase inhibitor and the other tamoxifen except that, after 2–3 years of tamoxifen, there appeared to be fewer such deaths with an aromatase inhibitor than with continuing tamoxifen—reassuringly for women who do not tolerate tamoxifen.

The most extreme recurrence reduction appeared to be in comparison C in which, after 2 years of tamoxifen, an aromatase inhibitor was compared with tamoxifen during years 5–9, as does 5 years of tamoxifen. The reduction in breast cancer mortality with aromatase inhibitor compared with tamoxifen is only slight, as expected in an already relatively good-prognosis population, but persists during years 0–4 and 5–9, significantly reducing 10-year breast cancer mortality. Overall 10-year mortality was also significantly reduced, even though about half the deaths were not due to breast cancer. Non-breast cancer death rates were similar with aromatase inhibitor and tamoxifen except that, after 2–3 years of tamoxifen, there appeared to be fewer such deaths with an aromatase inhibitor than with continuing tamoxifen. This finding was unexpected, not explained by any one cause, and not replicated in the other comparisons. Though likely to be a chance finding, it is reassuring for the safety of aromatase inhibitors.

**Bone fractures**

Bone fractures are a concern with aromatase inhibitors, though the absolute excess of about 0·5% per year might be partly explained by a bone-protective effect of...
Practitioners need to be aware of this complication as monitoring bone health and using bisphosphonates if indicated can reduce risk.\(^{22}\) The lower endometrial cancer incidence with aromatase inhibitor than tamoxifen of around 0-1% per year partly counterbalances the increased fracture risk.

With full compliance, the benefit of aromatase inhibitors over tamoxifen would probably have been somewhat greater than in our intention-to-treat analyses, as in addition to the usual levels of dropout in long-term trials, which might affect both groups similarly, substantial crossover of patients from tamoxifen to an aromatase inhibitor occurred in two trials,\(^{4,5}\) following reports that switching to an aromatase inhibitor after 2–3 years of tamoxifen reduces recurrence compared with continuing tamoxifen.\(^{11}\) The intention-to-treat analyses presented throughout this report take no account of dropouts or crossovers, so they underestimate the superiority of aromatase inhibitor over tamoxifen for breast cancer endpoints. Subsequent publications will investigate various analytic approaches (eg, as applied to BIG 1-98\(^{8}\)) to estimate the aromatase inhibitor effect that would be seen with full compliance.

Among the postmenopausal women in these trials there were no significant differences in the RR by age. Trials of aromatase inhibitors versus tamoxifen in premenopausal women treated with an ovarian suppressant\(^{21,26}\) were not included. Although age is not an independent correlate of distant recurrence or treatment efficacy, it is a major determinant of the life expectancy gain from avoiding distant recurrence. As subgroup analyses pooling data from all trials did not identify any patient or tumour characteristic that strongly predicted the RR, the key quantitative findings likely to be generalisable to future patients\(^{22}\) are the proportional risk reductions of around 30% in recurrence during the aromatase inhibitor versus tamoxifen comparison periods, and the proportional reduction of about 15% in the breast cancer mortality rate during the first decade.

We can infer from the present results the proportional reductions that would be achieved with 5 years of aromatase inhibitor compared with no adjuvant endocrine therapy (table). Treatment with tamoxifen for 5 years reduces recurrence by about half during years 0–4 and one-third during years 5–9, and reduces the breast cancer mortality rate by about 30% throughout the first decade and beyond.\(^{7}\) Therefore, 5 years of an aromatase inhibitor compared with no endocrine therapy would reduce breast cancer recurrence by about two-thirds during treatment and by about one-third during years 5–9, and would reduce the breast cancer mortality rate by around 40% throughout the first decade, and perhaps beyond. Though these proportional reductions in risk are approximately independent of nodal status, tumour grade, diameter, PR, and HER2 status, these prognostic factors substantially affect the absolute risk with no endocrine treatment, and hence substantially affect the absolute reduction in that risk produced by aromatase inhibitors.

Finally, the trials that involve starting endocrine treatment with an aromatase inhibitor rather than with tamoxifen collectively show a highly significant 30% recurrence reduction during years 0–1. The trials comparing 5 years of aromatase inhibitor with a switching strategy of 2–3 years of tamoxifen then aromatase inhibitor to year 5 provide no indication that this recurrence reduction during years 0–1 will later be lost, and it is likely that it would eventually translate into a slight survival improvement. However, in the 2014 ASCO guidelines on endocrine treatment of postmenopausal women with ER-positive early breast cancer, three of the four recommended options start with tamoxifen;\(^{22}\) a review seems appropriate.

**Contributors**

The EBCTCG secretariat (R Bradley, J Burrett, M Clarke, C Davies, F Duane, V Evans, I Gettins, J Godwin, R Gray, H Liu, P McGale, E MacKinnon, J McFigh, S James, P Morris, H Pan, R Petö, S Read, C Taylor, Y Wang, and Z Wang) identified trials, obtained datasets, and had full access to them; R Bradley, C Davies, R Gray, H Pan, and R Petö generated analyses. M Dowsett, R Bradley, J F Forbes, J Ingle, and R Gray drafted the report with advice from A Coates, J Cuzick, M Gnati, and R Petö. These and all other writing committee members (T Aihara, J Bliss, F Boccardo, A Coates, R Charles Coombes, P Dubosky, M Kaufmann, L Kilburn, F Perrone, D Rea, B Thürlimann, C van de Velde, C Davies, and H Pan) contributed to revising the report.
